7. Vitamin C

7.1 Introduction

Vitamin C (chemical names: ascorbic acid and ascorbate) is a six-carbon lactone which is synthesized from glucose by many animals. Vitamin C is synthesized in the liver in some mammals and in the kidney in birds and reptiles. However, several species—including humans, non-human primates, guinea pigs, Indian fruit bats, and Nepalese red-vented bulbuls—are unable to synthesize vitamin C. When there is insufficient vitamin C in the diet, humans suffer from the potentially lethal deficiency disease scurvy (1). Humans and primates lack the terminal enzyme in the biosynthetic pathway of ascorbic acid, L-gulonolactone oxidase, because the gene encoding for the enzyme has undergone substantial mutation so that no protein is produced (2).

7.2 Role of vitamin C in human metabolic processes7.2.1 Background biochemistry

Vitamin C is an electron donor (reducing agent or antioxidant), and probably all of its biochemical and molecular roles can be accounted for by this function. The potentially protective role of vitamin C as an antioxidant is discussed in the antioxidants chapter of this report (see Chapter 8).

7.2.2 Enzymatic functions

Vitamin C acts as an electron donor for 11 enzymes (3, 4). Three of those enzymes are found in fungi but not in humans or other mammals (5, 6) and are involved in reutilization pathways for pyrimidines and the deoxyribose moiety of deoxynucleosides. Of the eight remaining human enzymes, three participate in collagen hydroxylation (7-9) and two in carnitine biosynthesis (10, 11); of the three enzymes which participate in collagen hydroxylation, one is necessary for biosynthesis of the catecholamine norepinephrine (12, 13), one is necessary for amidation of peptide hormones (14, 15), and one is involved in tyrosine metabolism (4, 16).

Ascorbate interacts with enzymes having either monooxygenase or dioxygenase activity. The monooxygenases, dopamine β -monooxygenase and peptidyl-glycine α -monooxygenase, incorporate a single oxygen atom into a substrate, either a dopamine or a glycine-terminating peptide. The dioxygenases incorporate two oxygen atoms in two different ways: the enzyme 4-hydroxyphenylpyruvate dioxygenase incorporates two oxygen atoms into one product; the other dioxygenase incorporates one oxygen atom into succinate and one into the enzyme-specific substrate.

7.2.3 Miscellaneous functions

Concentrations of vitamin C appear to be high in gastric juice. Schorah et al. (17) found that the concentrations of vitamin C in gastric juice were severalfold higher (median, 249 μ mol/l; range, 43–909 μ mol/l) than those found in the plasma of the same normal subjects (median, 39 μ mol/l; range, 14–101 μ mol/l). Gastric juice vitamin C may prevent the formation of *N*-nitroso compounds, which are potentially mutagenic (18). High intakes of vitamin C correlate with reduced gastric cancer risk (19), but a cause-and-effect relationship has not been established. Vitamin C protects low-density lipoproteins ex vivo against oxidation and may function similarly in the blood (20) (see Chapter 8).

A common feature of vitamin C deficiency is anaemia. The antioxidant properties of vitamin C may stabilize folate in food and in plasma; increased excretion of oxidized folate derivatives in humans with scurvy has been reported (21). Vitamin C promotes absorption of soluble non-haem iron possibly by chelation or simply by maintaining the iron in the reduced (ferrous, Fe²⁺) form (22, 23). The effect can be achieved with the amounts of vitamin C obtained in foods. However, the amount of dietary vitamin C required to increase iron absorption ranges from 25 mg upwards and depends largely on the amount of inhibitors, such as phytates and polyphenols, present in the meal (24). (See Chapter 13 for further discussion.)

7.3 Consequences of vitamin C deficiency

From the 15th century, scurvy was dreaded by seamen and explorers forced to subsist for months on diets of dried beef and biscuits. Scurvy was described by the Crusaders during the sieges of numerous European cities, and was also a result of the famine in 19th century Ireland. Three important manifestations of scurvy—gingival changes, pain in the extremities, and haemorrhagic manifestations—precede oedema, ulcerations, and ultimately death. Skeletal and vascular lesions related to scurvy probably arise from a failure of osteoid formation. In infantile scurvy the changes are mainly at the sites of most active bone growth; characteristic signs are a pseudoparalysis of the limbs caused by extreme pain on movement and caused by haemorrhages under the periosteum, as well as swelling and haemorrhages of the gums surrounding erupting teeth (25). In adults, one of the early principle adverse effects of the collagen-related pathology may be impaired wound healing (26).

Vitamin C deficiency can be detected from early signs of clinical deficiency, such as the follicular hyperkeratosis, petechial haemorrhages, swollen or bleeding gums, and joint pain, or from the very low concentrations of ascorbate in plasma, blood, or leukocytes. The Sheffield studies (26, 27) and the later studies in Iowa (28, 29) were the first major attempts to quantify vitamin C requirements. The studies indicated that the amount of vitamin C required to prevent or cure early signs of deficiency is between 6.5 and 10 mg/day. This range represents the lowest physiological requirement. The Iowa studies (28, 29) and Kallner et al. (30) established that at tissue saturation, whole-body vitamin C content is approximately 20 mg/kg, or 1500 mg, and that during depletion vitamin C is lost at a rate of 3% of whole-body content per day.

Clinical signs of scurvy appear in men at intakes lower than 10 mg/day (27) or when the whole-body content falls below 300 mg (28). Such intakes are associated with plasma ascorbate concentrations below $11 \mu \text{mol/l}$ or leukocyte levels less than 2 nmol/10^8 cells. However, plasma concentrations fall to around $11 \mu \text{mol/l}$ even when dietary vitamin C is between 10 and 20 mg/day. At intakes greater than 25-35 mg/day, plasma concentrations start to rise steeply, indicating a greater availability of vitamin C for metabolic needs. In general, plasma ascorbate closely reflects the dietary intake and ranges between 20 and $80 \mu \text{mol/l}$. During infection or physical trauma, the number of circulating leukocytes increases and these take up vitamin C from the plasma (*31, 32*). Therefore, both plasma and leukocyte levels may not be very precise indicators of body content or status at such times. However, leukocyte ascorbate most of the time and only in the period immediately after the onset of an infection are both values unreliable.

Intestinal absorption of vitamin C is by an active, sodium-dependent, energy-requiring, carrier-mediated transport mechanism (33) and as intake increases, the tissues become progressively more saturated. The physiologically efficient, renal-tubular reabsorption mechanism retains vitamin C in the tissues up to a whole-body content of ascorbate of about 20 mg/kg body weight (30). However, under steady-state conditions, as intake rises from around 100 mg/day there is an increase in urinary output so that at 1000 mg/day almost all absorbed vitamin C is excreted (34, 35).

7.4 Populations at risk for vitamin C deficiency

The populations at risk of vitamin C deficiency are those for whom the fruit and vegetable supply is minimal. Epidemics of scurvy are associated with famine and war, when people are forced to become refugees and food supply is small and irregular. Persons in whom the total body vitamin C content is saturated (i.e. 20mg/kg body weight) can subsist without vitamin C for approximately 2 months before the appearance of clinical signs, and as little as 6.5–10mg/day of vitamin C will prevent the appearance of scurvy. In general, vitamin C status will reflect the regularity of fruit and vegetable consumption; however, socioeconomic conditions are also factors as intake is determined not just by availability of food, but by cultural preferences and cost.

In Europe and the United States an adequate intake of vitamin C is indicated by the results of various national surveys (36-38). In Germany and the United Kingdom, the mean dietary intakes of vitamin C in adult men and women were 75 and 72 mg/day (36), and 87 and 76 mg/day (37), respectively. In addition, a recent survey of elderly men and women in the United Kingdom reported vitamin C intakes of 72 (SD, 61) and 68 (SD, 60) mg/day, respectively (39). In the United States, in the third National Health and Nutrition Examination Survey (38), the median consumption of vitamin C from foods during the years 1988-91 was 73 and 84 mg/day in men and women, respectively. In all of these studies there was a wide variation in vitamin C intake. In the United States 25–30% of the population consumed less than 2.5 servings of fruit and vegetables daily. Likewise, a survey of Latin American children suggested that less than 15% consumed the recommended intake of fruits and vegetables (40). It is not possible to relate servings of fruits and vegetables to an exact amount of vitamin C, but the WHO dietary goal of 400 g/day (41), aimed at providing sufficient vitamin C to meet the 1970 FAO/WHO guidelines-that is, approximately 20-30 mg/day-and lower the risk of chronic disease. The WHO goal has been roughly translated into the recommendation of five portions of fruits and vegetables per day (42).

Reports from India show that the available supply of vitamin C is 43 mg/capita/day, and in the different states of India it ranges from 27 to 66 mg/day. In one study, low-income children consumed as little as 8.2 mg/day of vitamin C in contrast to a well-to-do group of children where the intake was 35.4 mg/day (43). Other studies done in developing countries found plasma vitamin C concentrations lower than those reported for developed countries, for example, 20–27 μ mol/l for apparently healthy adolescent boys and girls in China and 3–54 μ mol/l (median, 14 μ mol/l) for similarly aged Gambian nurses (44, 45), although values obtained in a group of adults from a rural district in northern Thailand were quite acceptable (median, 44 μ mol/l; range, 17–118 μ mol/l) (46). However, it is difficult to assess the extent to which subclinical infections are lowering the plasma vitamin C concentrations seen in such countries.

Claims for a positive association between vitamin C consumption and health status are frequently made, but results from intervention studies are inconsistent. Low plasma concentrations are reported in patients with diabetes (47) and infections (48) and in smokers (49), but the relative contribution of diet and stress to these situations is uncertain (see Chapter 8 on antioxidants). Epidemiological studies indicate that diets with a high vitamin C content have been associated with lower cancer risk, especially for cancers of the oral cavity, oesophagus, stomach, colon, and lung (39, 50-52). However, there appears to be no effect of consumption of vitamin C supplements on the development of colorectal adenoma and stomach cancer (52-54), and data on the effect of vitamin C supplementation on coronary heart disease and cataract development are conflicting (55–74). Currently there is no consistent evidence from population studies that heart disease, cancers, or cataract development are specifically associated with vitamin C status. This of course does not preclude the possibility that other components in vitamin C-rich fruits and vegetables provide health benefits, but it is not yet possible to isolate such effects from other factors such as lifestyle patterns of people who have a high vitamin C intake.

7.5 Dietary sources of vitamin C and limitations to vitamin C supply

Ascorbate is found in many fruits and vegetables (75). Citrus fruits and juices are particularly rich sources of vitamin C but other fruits including cantaloupe and honeydew melons, cherries, kiwi fruits, mangoes, papaya, strawberries, tangelo, tomatoes, and water melon also contain variable amounts of vitamin C. Vegetables such as cabbage, broccoli, Brussels sprouts, bean sprouts, cauliflower, kale, mustard greens, red and green peppers, peas, and potatoes may be more important sources of vitamin C than fruits, given that the vegetable supply often extends for longer periods during the year than does the fruit supply.

In many developing countries, the supply of vitamin C is often determined by seasonal factors (i.e. the availability of water, time, and labour for the management of household gardens and the short harvesting season of many fruits). For example, mean monthly ascorbate intakes ranged from 0 to 115 mg/day in one Gambian community in which peak intakes coincided with the seasonal duration of the mango crop and to a lesser extent with orange and grapefruit harvests. These fluctuations in dietary ascorbate intake were closely reflected by corresponding variations in plasma ascorbate (11.4–68.4 μ mol/l) and human milk ascorbate (143–342 μ mol/l) (76).

Vitamin C is very labile, and the loss of vitamin C on boiling milk

provides one dramatic example of a cause of infantile scurvy. The vitamin C content of food is thus strongly influenced by season, transport to market, length of time on the shelf and in storage, cooking practices, and the chlorination of the water used in cooking. Cutting or bruising of produce releases ascorbate oxidase. Blanching techniques inactivate the oxidase enzyme and help to preserve ascorbate; lowering the pH of a food will similarly achieve this, as in the preparation of sauerkraut (pickled cabbage). In contrast, heating and exposure to copper or iron or to mildly alkaline conditions destroys the vitamin, and too much water can leach it from the tissues during cooking.

It is important to realize that the amount of vitamin C in a food is usually not the major determinant of a food's importance for supply, but rather regularity of intake. For example, in countries where the potato is an important staple food and refrigeration facilities are limited, seasonal variations in plasma ascorbate are due to the considerable deterioration in the potato's vitamin C content during storage; the content can decrease from 30 to 8 mg/100g over 8–9 months (77). Such data illustrate the important contribution the potato can make to human vitamin C requirements even though the potato's vitamin C concentration is low.

An extensive study has been made of losses of vitamin C during the packaging, storage, and cooking of blended foods (i.e. maize and soya-based relief foods). Data from a United States international development programme show that vitamin C losses from packaging and storage in polythene bags of such relief foods are much less significant than the 52–82% losses attributable to conventional cooking procedures (78).

7.6 Evidence used to derive recommended intakes of vitamin C

7.6.1 Adults

At saturation the whole body content of ascorbate in adult males is approximately 20 mg/kg, or 1500 mg. Clinical signs of scurvy appear when the wholebody content falls below 300–400 mg, and the last signs disappear when the body content reaches about 1000 mg (28, 30). Human studies have also established that ascorbate in the whole body is catabolized at an approximate rate of 3% per day (2.9% per day, SD, 0.6) (29).

There is a sigmoidal relationship between intake and plasma concentrations of vitamin C (79). Below intakes of 30 mg/day, plasma concentrations are around $11 \mu \text{mol/l}$. Above this intake, plasma concentrations increase steeply to $60 \mu \text{mol/l}$ and plateau at around $80 \mu \text{mol/l}$, which represents the renal threshold. Under near steady-state conditions, plateau concentrations of vitamin C are achieved by intakes in excess of 200 mg/day (Figure 7.1) (34).

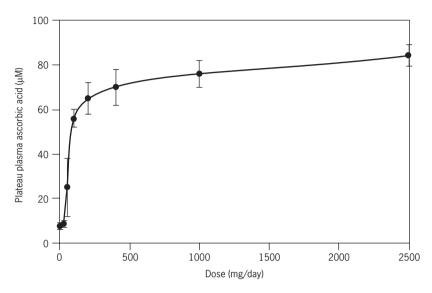

FIGURE 7.1 Plasma vitamin C concentrations achieve steady state at intakes in excess of 200 mg/day

Source: reference (34).

At low doses dietary vitamin C is almost completely absorbed, but over the range of usual dietary intakes (30–180 mg/day), absorption may decrease to 75% because of competing factors in the food (*35*, *80*).

A body content of 900 mg falls halfway between tissue saturation (1500 mg) and the point at which clinical signs of scurvy appear (300-400 mg). Assuming an absorption efficiency of 85%, and a catabolic rate of 2.9%, the average intake of vitamin C can be calculated as:

 $900 \times 2.9/100 \times 100/85 = 30.7 \text{ mg/day}.$

This value can be rounded to 30 mg/day. The recommended nutrient intake (RNI) would therefore be:

 $900 \times (2.9 + 1.2)/100 \times 100/85 = 43.4$ mg/day.

This can be rounded to 45 mg/day.

An RNI of 45 mg would achieve 50% saturation in the tissues in 97.5% of adult males. An intake of 45 mg vitamin C will produce a plasma ascorbate concentration near the base of the steep slope of the diet-plasma dose response curve (Figure 7.1). No turnover studies have been done in women, but from the smaller body size and whole body content of women, requirements might be expected to be lower. However, in depletion studies plasma concentrations fell more rapidly in women than in men (81). It would seem prudent, therefore, to make the same recommendation for non-pregnant, non-lactating women as for men. Thus, an intake of 45 mg/day will ensure that measurable amounts of ascorbate will be present in the plasma of most people and will be available to supply tissue requirements for metabolism or repair at sites of depletion or damage. A whole-body content of around 900 mg of vitamin C would provide at least one month's safety interval, even for a zero intake, before the body content falls to 300 mg (82).

The Sheffield (27) and Iowa studies (28) referred to earlier indicated that the minimum amount of vitamin C needed to cure scurvy in men is less than 10mg/day. This level however, is not sufficient to provide measurable amounts of ascorbate in plasma and leukocyte cells, which will remain low. As indicated above, no studies have been done on women and minimum requirements to protect non-pregnant and non-lactating women against scurvy might be slightly lower than those for men. Although 10mg/day will protect against scurvy, this amount provides no safety margin against further losses of ascorbate. The mean requirement is therefore calculated by interpolation between 10 and 45 mg/day, at an intake of 25–30 mg/day.

7.6.2 Pregnant and lactating women

During pregnancy there is a moderate increased need for vitamin C, particularly during the last trimester. Eight mg/day of vitamin C is reported to be sufficient to prevent scorbutic signs in infants aged 4–17 months (83). Therefore, an extra 10 mg/day throughout pregnancy should enable reserves to accumulate to meet the extra needs of the growing fetus in the last trimester.

During lactation, however, 20 mg/day of vitamin C is secreted in milk. For an assumed absorption efficiency of 85%, maternal needs will require an extra 25 mg per day. It is therefore recommended that the RNI should be set at 70 mg/day to fulfil the needs of both the mother and infant during lactation.

7.6.3 Children

As mentioned above, 8 mg/day of vitamin C is sufficient to prevent scorbutic signs in infants (83). The mean concentration of vitamin C in mature human milk is estimated to be 40 mg/l (SD, 10) (84), but the amount of vitamin C in human milk appears to reflect maternal dietary intake and not the infant's needs (82, 83, 85). The RNI for infants aged 0–6 months is therefore set, somewhat arbitrarily, at 25 mg/day, and the RNI is gradually increased as children get older.

7.6.4 Elderly

Elderly people frequently have low plasma ascorbate values and intakes lower than those in younger people, often because of problems of poor dentition or mobility (*86*). Elderly people are also more likely to have underlying subclinical diseases, which can also influence plasma ascorbate concentrations (see Chapter 8 on antioxidants). It has been suggested, however, that the requirements of elderly people do not differ substantially from those of younger people in the absence of pathology which may influence absorption or renal functioning (*82*). The RNIs for the elderly are therefore the same as those for adults (45 mg/day).

7.6.5 Smokers

Kallner et al. (87) reported that the turnover of vitamin C in smokers was 50% greater than that in non-smokers. However, there is no evidence that the health of smokers would be influenced in any way by increasing their RNI. The Expert Consultation therefore found no justification for making a separate RNI for smokers.

7.7 Recommended nutrient intakes for vitamin C

Table 7.1 presents a summary of the discussed RNIs for vitamin C by group.

Group	RNI (mg/day) ^a
Infants and children	
0–6 months	25
7–12 months	30 ^b
1–3 years	30 ^b
4–6 years	30 ^b
7–9 years	35⁵
Adolescents	
10–18 years	40 ^b
Adults	
19–65 years	45
65+ years	45
Pregnant women	55
Lactating women	70

TABLE 7.1 **Recommended nutrient intakes (RNIs) for vitamin C,** by group

^a Amount required to half saturate body tissues with vitamin C in 97.5% of the population. Larger amounts may often be required to ensure an adequate absorption of non-haem iron.

^b Arbitrary values.

7.8 Toxicity

The potential toxicity of excessive doses of supplemental vitamin C relates to intraintestinal events and to the effects of metabolites in the urinary system. Intakes of 2-3 g/day of vitamin C produce unpleasant diarrhoea from the osmotic effects of the unabsorbed vitamin in the intestinal lumen in most people (88). Gastrointestinal disturbances can occur after ingestion of as little as 1g because approximately half of this amount would not be absorbed at this dose (35).

Oxalate is an end-product of ascorbate catabolism and plays an important role in kidney stone formation. Excessive daily amounts of vitamin C produce hyperoxaluria. In four volunteers who received vitamin C in doses ranging from 5 to 10g/day, mean urinary oxalate excretion approximately doubled from 50 to 87 mg/day (range, 60–126 mg/day) (89). However, the risk of oxalate stone formation may become significant at high intakes of vitamin C (>1g) (90), particularly in subjects with high amounts of urinary calcium (89).

Vitamin C may precipitate haemolysis in some people, including those with glucose-6-phosphate dehydrogenase deficiency (91), paroxysmal nocturnal haemaglobinuria (92), or other conditions where increased risk of red cell haemolysis may occur or where protection against the removal of the products of iron metabolism may be impaired, as in people with the haptoglobin Hp2-2 phenotype (93). Of these, only the haptoglobin Hp2-2 condition was associated with abnormal vitamin C metabolism (lower plasma ascorbate than expected) and only in cases where intake of vitamin C was provided mainly from dietary sources.

On the basis of the above, the Consultation agreed that 1 g of vitamin C appears to be the advisable upper limit of dietary intake per day.

7.9 Recommendations for future research

Research is needed to gain a better understanding of the following:

- functions of endogenous gastric ascorbate and its effect on iron absorption;
- functional measurements of vitamin C status which reflect the whole-body content of vitamin C and which are not influenced by infection;
- reasons for the vitamin C uptake by granulocytes which is associated with infection.
